Abstract. The standard field-theoretical approach to the slow-roll inflation is introduced. We then show as, in order to calculate the mean square of the canonical gauge invariant quantum fluctuations associated to a generic field, the logarithm of the scale factor has to be used as the time variable in the Fokker-Planck equation in the stochastic approach. Then we compute the growth of different test fields with a small effective mass during slow-roll inflationary models, comparing the results with the one for the gauge invariant canonical fluctuation associated to the inflaton, the Mukhanov variable. We find that in most of the single fields inflationary models such fluctuation grows faster than any test field with a non-negative effective mass, with the exception of hybrid models.

I. INTRODUCTION

The theory of quantum fields in an expanding universe has evolved from its pioneering years [1] into a necessary tool in order to describe the Universe on large scales. The de Sitter background - characterized by the Hubble parameter $H \equiv \dot{a}/a$ being constant in time (for the flat spatial slice), where $a(t)$ is the scale factor of a Friedmann-Lemaitre-Robertson-Walker (FLRW) cosmological model - has been the main arena to compute quantum effects even before becoming a pillar of our understanding of the early inflationary stage and of the recent acceleration of the Universe.

However, while $|\dot{H}| \ll H^2$ for any inflationary model, $\dot{H}$ may not become zero in a viable model, apart from some isolated moments of time. Indeed, the standard slow-roll expression for the power spectrum of the adiabatic mode of primordial scalar (density) perturbations becomes infinite, i.e., meaningless, if $\dot{H}$ becomes zero during inflation. Therefore, the study of quantum effects in a nearly de Sitter stage with $\dot{H} \neq 0$, in particular, when the total change in H during inflation is not small compared with its value during the last e-folds of inflation [2, 3, 4, 5, 6] (see also the recent papers [7, 8, 9]), is not of just pure theoretical interest.

In general inflationary model quantum scalar field can be split into a long wave (coarse grained) component and a short-wave (perturbative) one. Then it can be proved that the former component effectively becomes quasi-classical, though random (i.e. all non-commutative parts of it may be neglected), and it experiences a random walk described by the stochastic inflation approach [10].

However, it should be emphasized that just because of the non-perturbative nature of the stochastic approach to inflation, it is based on a number of heuristic approximations. Therefore, it is very important to check, whenever possible, results obtained by its application using the standard perturbative QFT in curved space-time.

In this paper we discuss, following the result of [5, 6], the diffusion equation for general scalar fluctuations in a generic model of inflation. On using the results obtained by field theory methods, we show that the stochastic diffusion equation for the canonical gauge invariant variables associated with these generic scalar fluctuations should be formulated in terms of the number of e-folds N.

We then tackle in more detail the moduli problem issue. Following [5, 6] we consider the stochastic growth of different test fields as massive minimally coupled scalar fields, massless non-minimally coupled scalar fields and moduli with an effective mass $\propto H^2$, in different inflationary models. On the other hand, it is known [3] that the mean square of gauge invariant Mukhanov variable [11] grows; it is therefore interesting to compare the amplification of the test fields above not only with the background inflaton dynamics, but also with the stochastic growth of this gauge invariant fluctuation. This comparison aims for a self-consistent understanding of quantum foam during inflation.

The paper is organized as follows. In Section II we describe a two field model with two generic self-interacting potentials, each of them depends on one field only, introducing the field theory approach. In Section III we examine the stochastic approach for such two field model. In Section IV we derive the equations to obtain the stochastic growth of the test fields considered and of the gauge invariant Mukhanov variable. In Section V we consider four representative cases of the inflationary *"zoo"* for which we calculate the growth of the fields and compare different results. In Section VI we present our conclusions.

II. INFLATION AND FIELD-THEORETICAL APPROACH

Let us consider, in a spatially flat FLRW background geometry, a two field model in which the dynamics is driven by a minimally coupled inflaton ϕ and a minimally coupled scalar field χ is present. We shall neglect the χ energy density and pressure in the background FLRW equations.

The action is given by

$$S = \int d^4x\sqrt{-g}\left[\frac{R}{16\pi G} - \frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi) - \frac{1}{2}g^{\mu\nu}\partial_\mu\chi\partial_\nu\chi - \bar{V}(\chi)\right] \quad (1)$$

and we can expand our background fields $\{\phi,\, \chi,\, g_{\mu\nu}\}$ up to second order in the non-homogeneous perturbations, without fixing any gauge, as follows:

$$\phi(t,\vec{x}) = \phi^{(0)}(t) + \phi^{(1)}(t,\vec{x}) + \phi^{(2)}(t,\vec{x}) \;\; , \;\; \chi(t,\vec{x}) = \chi^{(0)}(t) + \chi^{(1)}(t,\vec{x}) + \chi^{(2)}(t,\vec{x})\,, \quad (2)$$

$$g_{00} = -1 - 2\alpha^{(1)} - 2\alpha^{(2)}, \qquad g_{i0} = -\frac{a}{2}\left(\beta^{(1)}_{,i} + \beta^{(2)}_{,i}\right),$$
$$g_{ij} = a^2\left[\delta_{ij}\left(1 - 2\psi^{(1)} - 2\psi^{(2)}\right) + D_{ij}(E^{(1)} + E^{(2)})\right],$$

where $D_{ij} = \partial_i\partial_j - \delta_{ij}(\nabla^2/3)$, and we neglect vector and tensor perturbations.

The degrees of freedom above are in part redundant. To obtain a set of well defined equations (Einstein equations + equations of motion of the matter sector), order by order, we have, for example, to set to zero two modes of scalar perturbations. The choice of such variables is called a choice of "gauge".

In this case, the study of the scalar sector can be reduced to the study of two different gauge invariant variables. Let us choice, as one of these, the so-called Mukhanov variable Q [11], which is usually used to canonically quantize the Einstein-Klein-Gordon Lagrangian. The Mukhanov variable can be seen, order by order, as the scalar field fluctuations $\phi^{(n)}$ on uniform curvature hypersurface (see, for example, [12]). To first order, one obtains

$$Q^{(1)} = \phi^{(1)} + \frac{\dot{\phi}^{(0)}}{H}\left(\psi^{(1)} + \frac{1}{6}\nabla^2 E^{(1)}\right). \tag{3}$$

In the same way we can define, order by order, the second gauge invariant variable as the scalar field fluctuations χ on uniform curvature hypersurface. We will call this Q_χ and, to first order, it is given by

$$Q^{(1)}_\chi = \chi^{(1)} + \frac{\dot{\chi}^{(0)}}{H}\left(\psi^{(1)} + \frac{1}{6}\nabla^2 E^{(1)}\right). \tag{4}$$

A particular choice of gauge is the one that fix to zero ψ and E to all orders. Such a gauge is called the Uniform Curvature Gauge (UCG) and in this one obtains

$$Q^{(n)} = \phi^{(n)} \quad , \quad Q^{(n)}_\chi = \chi^{(n)} \tag{5}$$

In the UCG, at the leading order in the slow-roll approximation and in the long-wavelength limit, the equation of motions of the scalar fields ϕ and χ can be obtained, order by order, from the expansion around the classical solution of

$$\frac{d\phi}{dN} = -\frac{V_\phi}{3H(\phi)^2} \quad , \quad \frac{d\chi}{dN} = -\frac{\bar{V}_\chi}{3H(\phi)^2}, \tag{6}$$

with $N = \log(a(t)/a(t_i))$ being the number of e-folds.

So for the inflaton field we have

$$\ddot{\phi}^{(0)} + 3H\dot{\phi}^{(0)} + V_\phi = 0 \quad , \quad 3H\dot{\phi}^{(1)} + \left[V_{\phi\phi} - \frac{V_\phi^2}{3H^2M_{pl}^2}\right]\phi^{(1)} = 0,$$
$$3H\dot{\phi}^{(2)} + \left[V_{\phi\phi} - \frac{V_\phi^2}{3H^2M_{pl}^2}\right]\phi^{(2)} = -\frac{1}{2}\left[V_{\phi\phi\phi} - \frac{V_{\phi\phi}V_\phi}{H^2M_{\rm pl}^2} + \frac{2V_\phi^3}{9H^4M_{\rm pl}^4}\right]\phi^{(1)\,2},$$

while for the field χ one obtains

$$\ddot{\chi}^{(0)} + 3H\dot{\chi}^{(0)} + \bar{V}_{\chi} = 0 \quad , \quad 3H\dot{\chi}^{(1)} + \bar{V}_{\chi\chi}\chi^{(1)} = 2\frac{H_{\phi}}{H}\bar{V}_{\chi}\varphi^{(1)}$$

$$3H\dot{\chi}^{(2)} + \bar{V}_{\chi\chi}\chi^{(2)} = 2\frac{H_{\phi}}{H}\bar{V}_{\chi}\varphi^{(2)} + \left[\frac{H_{\phi\phi}}{H} - 3\left(\frac{H_{\phi}}{H}\right)^{2}\right]\bar{V}_{\chi}\varphi^{(1)2} + 2\bar{V}_{\chi\chi}\frac{H_{\phi}}{H}\varphi^{(1)}\chi^{(1)} - \frac{\bar{V}_{\chi\chi\chi}}{2}\chi^{(1)2}$$

III. STOCHASTIC GROWTH OF QUANTUM FLUCTUATION

The results in the previous section suggest that one has to choose the time variable $N = \int H(t)dt$ in the Langevin stochastic equation for the large-scale part of ϕ or χ.

Following [10], the number of e-folds N was considered as a time variable in the stochastic Langevin equation in a number of papers, e.g. in [13] and most recently in [14], while in many other ones the proper time t was used, e.g. in [15, 16, 17, 18]. This usage of different time variables should not be mixed with the invariance of all physical results with respect to a (deterministic) time reparametrization $t \to f(t)$ which is trivially satisfied after taking the corresponding change in the metric lapse function into account. In contrast, the transformation from t to N made using the stochastic function $H(\phi(t))$ leads to a physically different stochastic process with another probability distribution. The new statement made in [5, 6] is that one *should* use the N variable when calculating mean squares of any gauge invariant quantity containing metric fluctuations like the Mukhanov variable Q or the gauge invariant variable Q_{χ}. Otherwise, incorrect results would be obtained using the stochastic approach which would then not coincide with those obtained using perturbative QFT methods.

The Langevin stochastic equations can so be written as

$$\frac{d\phi}{dN} = -\frac{V_{\phi}}{3H^{2}} + \frac{f_{\phi}}{H}\,, \qquad \frac{d\chi}{dN} = -\frac{\bar{V}_{\chi}}{3H^{2}} + \frac{f_{\chi}}{H}\,,$$
$$\langle f_{\phi}(N_1) f_{\phi}(N_2)\rangle = \frac{H^4}{4\pi^2}\,\delta(N_1 - N_2)\,, \quad \langle f_{\chi}(N_1) f_{\chi}(N_2)\rangle = \frac{H^4}{4\pi^2}\,\delta(N_1 - N_2)\,,$$

where $H^2 = V(\phi(t))/3M_{pl}^2$ is a function of ϕ. The stochastic noise terms are given, to the leading order in the slow-roll approximation ($\varepsilon = \frac{M_{pl}^2}{2}\left(\frac{V_{\phi}}{V}\right)^2$), by

$$\begin{aligned} f_{\phi}(t,\mathbf{x}) &= \varepsilon a H^2 \int \frac{d^3k}{(2\pi)^{3/2}}\delta(k - \varepsilon a H)\left[\hat{a}_k \phi_k(t) e^{-i\mathbf{k}\cdot\mathbf{x}} + \hat{a}_k^{\dagger}\phi_k^{*}(t) e^{+i\mathbf{k}\cdot\mathbf{x}}\right]\,, \\ f_{\chi}(t,\mathbf{x}) &= \varepsilon a H^2 \int \frac{d^3k}{(2\pi)^{3/2}}\delta(k - \varepsilon a H)\left[\hat{b}_k \chi_k(t) e^{-i\mathbf{k}\cdot\mathbf{x}} + \hat{b}_k^{\dagger}\chi_k^{*}(t) e^{+i\mathbf{k}\cdot\mathbf{x}}\right]\,. \end{aligned}$$

On expanding to first order one obtains for the inflaton fluctuation [5]

$$\frac{d}{dN}\phi^{(1)} + 2M_{pl}^2\left(\frac{H_{\phi\phi}}{H} - \frac{H_{\phi}^2}{H^2}\right)\phi^{(1)} = \frac{f_{\phi}}{H}\,, \tag{7}$$

which gives the following result for the growth of quantum fluctuations

$$\langle(\phi^{(1)})^2\rangle = \frac{1}{4\pi^2}\left(\frac{V_\phi}{V}\right)^2 \int_{t_i}^{t} dt' H^3 \left(\frac{V}{V_\phi}\right)^2 . \tag{8}$$

In the same way, to second order, we can obtain [5]

$$\langle\phi^{(2)}\rangle=\left(\frac{V_\phi}{V}\right)\int_{t_i}^{t}dt'\left(\frac{V}{V_\phi}\right)\left\{\frac{H^3}{16\pi^2}\left(\frac{V_\phi}{V}\right)+\frac{1}{2}\left[-\frac{1}{3H}V_{\phi\phi\phi}+\left(\frac{1}{H}V_{\phi\phi}+4\frac{\dot{H}}{H}\right)\frac{V_\phi}{V}\right]\langle(\phi^{(1)})^2\rangle\right\} . \tag{9}$$

On the other hand for the growth of quantum χ fluctuations one obtains [6]

$$\langle\chi^{(1)2}\rangle = \frac{\bar{V}_\chi^2}{4\pi^2}\int_{t_i}^{t} d\tau \left[\frac{H(\tau)^3}{V_\chi(\tau)^2} - \frac{4}{9M_{pl}^2}\int_{t_i}^{\tau} d\eta \frac{\dot{H}(\tau)}{H(\tau)^3}\frac{\dot{H}(\eta)}{H(\eta)^3}\int_{t_i}^{\eta} d\sigma \frac{H(\sigma)^5}{\dot{H}(\sigma)}\right] \tag{10}$$

$$\langle\chi^{(2)}\rangle=\bar{V}_\chi\int_{t_i}^{t}d\tau\left[\frac{2}{3}\frac{H_\phi}{H^2}\langle\varphi^{(2)}\rangle-\frac{1}{6H}\frac{\bar{V}_{\chi\chi\chi}}{V_\chi}\langle\chi^{(1)2}\rangle+\frac{2}{3}\frac{H_\phi}{H^2}\frac{\bar{V}_{\chi\chi}}{V_\chi}\langle\varphi^{(1)}\chi^{(1)}\rangle+\frac{1}{3}\left(\frac{H_{\phi\phi}}{H^2}-3\frac{H_\phi^2}{H^3}\right)\langle\varphi^{(1)2}\rangle\right] \tag{11}$$

where

$$\langle\varphi^{(1)}\chi^{(1)}\rangle = -\frac{\bar{V}_\chi}{12\pi^2}\frac{\dot{\phi}}{HM_{pl}^2}\int_{t_i}^{t} d\tau \int_{\tau}^{t} d\eta \left[\frac{H(\tau)^5}{\dot{H}(\tau)}\frac{\dot{H}(\eta)}{H(\eta)^3}\right] \tag{12}$$

IV. TEST FIELDS AND MUKHANOV VARIABLE

We shall consider now three different test scalar fields, with a small effective mass and a zero homogeneous expectation value, and the canonical gauge invariant inflaton fluctuation described by the Mukhanov variable. In this particular limit the first order fluctuations $\chi^{(1)}$ will be always gauge invariant and coincident with $Q_\chi^{(1)}$, independently from the gauge chosen.

The stochastic growth of $\chi^{(1)}$ can be obtained from Eq.(10) in the limit $\chi^{(0)} = 0$. In particular $\langle\chi^{(1)2}\rangle$ and $\langle Q^{(1)2}\rangle$ will be obtained under the natural assumption of the absence of particles in the in-vacuum state, more exactly that each Fourier mode **k** of the quantum fields were in the adiabatic vacuum state deep inside the Hubble radius and long before the first Hubble radius crossing during inflation.

Test scalar field with a constant mass m_χ

The stochastic equation is

$$\frac{d\langle\chi^{(1)2}\rangle}{dN} + \frac{2m_\chi^2}{3H(N)^2}\langle\chi^{(1)2}\rangle = \frac{H^2(N)}{4\pi^2} . \tag{13}$$

Its general solution is

$$\langle\chi^{(1)\,2}\rangle = \left(\int_{N_i}^{N} dn \frac{H^2(n)}{4\pi^2} e^{\int_{N_i}^{n} \frac{2m_\chi^2}{3H^2(\tilde{n})} d\tilde{n}}\right) e^{-\int_{N_i}^{N} \frac{2m_\chi^2}{3H^2(n)} dn}\,, \tag{14}$$

where we have assumed $\langle\chi^{(1)\,2}\rangle(N_i) = 0$ (we shall adopt the same choice afterwards).

Test scalar field with $m_\chi^2 = cH^2$

If $|c| \ll 1$ the stochastic equation is:

$$\frac{d\langle\chi^{(1)\,2}\rangle}{dN} + \frac{2c}{3}\langle\chi^{(1)\,2}\rangle = \frac{H^2(N)}{4\pi^2}\,. \tag{15}$$

Its general solution is

$$\langle\chi^{(1)\,2}\rangle = \left(\int_{N_i}^{N} dn \frac{H^2(n)}{4\pi^2} e^{\frac{2}{3}cn}\right) e^{-\frac{2}{3}cN}\,. \tag{16}$$

Massless non-minimally coupled test scalar field

The stochastic equation is:

$$\frac{d\langle\chi^{(1)\,2}\rangle}{dN} + 4\xi(2-\varepsilon)\langle\chi^{(1)\,2}\rangle = \frac{H^2(N)}{4\pi^2}\,, \tag{17}$$

where ξ is the non-minimal coupling to the Ricci scalar R and we assume that $|\xi| \ll 1$ (however, ξN may be large).

The term in the action proportional to $\xi\chi^2 R$ gives an effective time dependent mass $m_\chi^2 = 6\xi H^2(2-\varepsilon)$ where $\varepsilon = -\dot{H}/H^2$.

Its general solution is

$$\langle\chi^{(1)\,2}\rangle = \left(\int_{N_i}^{N} dn \frac{H^{2+4\xi}(n)}{4\pi^2 H_i^{4\xi}} e^{8\xi n}\right) \left(\frac{H_i}{H(N)}\right)^{4\xi} e^{-8\xi N}\,. \tag{18}$$

Mukhanov variable

The results for the test fields should be compared with the growth of the canonical gauge invariant inflaton fluctuation, namely the Mukhanov variable, $Q^{(1)}$. The evolution equation for $\langle Q^{(1)\,2}\rangle$ found in [5] can be re-written as [6]:

$$\frac{d\langle Q^{(1)\,2}\rangle_{\rm REN}}{dN} + 2\,(\eta - 2\varepsilon)\,\langle Q^{(1)\,2}\rangle_{\rm REN} = \frac{H^2(t)}{4\pi^2}\,, \tag{19}$$

where $\eta = M_{\rm pl}^2 \frac{V_{\phi\phi}}{V}$.

In Eq. (19) the positivity of $\eta - 2\varepsilon$ is not determined by the convexity of the potential, i.e. $V_{\phi\phi} > 0$, as we would expect in the absence of metric perturbations. The threshold corresponds to the condition $\frac{d}{d\phi}\left(\frac{V_\phi}{V}\right) > 0$ on the potential.

With the use of the slow-roll expressions for the scalar spectral index $n_s = 1 - 6\varepsilon + 2\eta$ and for the tensor-to-scalar ratio $r = 16\varepsilon$, Eq. (19) can be rewritten as:

$$\frac{d\langle Q^{(1)\,2}\rangle}{dN} + \left(n_s - 1 + \frac{r}{8}\right)\langle Q^{(1)\,2}\rangle = \frac{H^2(t)}{4\pi^2}\,. \tag{20}$$

Eq. (20) tell us that power-law inflation, for which $n_s - 1 = -r/8$ holds, lies at the threshold between two opposite behaviors. We note that Eq. (20) is the same for a modulus with the mass $m_\chi^2 = cH^2$ and $c = 3(n_s - 1 + r/8)/2$: below the power-law inflation line Mukhanov variable behaves as a modulus with negative c.

The solution of Eq. (19) is

$$\langle Q^{(1)\,2}\rangle = \frac{\varepsilon(N)}{4\pi^2}\int^N dn \frac{H^2(n)}{\varepsilon(n)}\,, \tag{21}$$

where we have assumed $\langle Q^{(1)\,2}\rangle(N_i) = 0$.

V. INFLATIONARY MODELS AND RESULTS

The detailed evolution of the expansion during the accelerated stage depends on the inflaton potential and so does the growth of quantum fluctuations. For this reason we consider in the following four different potentials which are representative of the *"inflationary zoo"*. Since we shall study the growth of quantum fluctuations as a function of N, the evolution of the Hubble parameter H has to be expressed as a function of N, too.

The first obvious model is chaotic quadratic inflation, which we have also used in our previous investigations [2, 3, 4]:

$$V(\phi) = \frac{m^2}{2}\phi^2 \quad \text{with} \quad H^2 \simeq H_i^2 - \frac{2}{3}m^2 N \quad , \quad \dot\phi \simeq -\sqrt{\frac{2}{3}}mM_{\rm pl}\,, \tag{22}$$

where $M_{pl}^{-2} = 8\pi G$. Let us note that in the numerical results presented in the figures all dimensional quantities have been rescaled w.r.t. $m_{pl} = M_{pl}\sqrt{8\pi}$.

As another large field inflationary model we consider an exponential potential

$$V = V_0 e^{-\frac{\lambda}{M_{\rm pl}}\phi} \quad \text{with} \quad a(t) = \left(\frac{t}{t_i}\right)^p \quad , \quad H(t) = \frac{p}{t} \tag{23}$$

with $p = 2/\lambda^2$ [19]. The slow-roll conditions are well satisfied for $p >> 1$, and one obtains

$$H = H_i e^{-N/p} = \frac{p}{t_i}e^{-N/p} \quad , \quad \phi = \sqrt{\frac{2}{p}}M_{pl}N + \phi_i\,. \tag{24}$$

We then consider the case of a quadratic potential (of arbitrary sign) uplifted with an offset V_0:

$$V(\phi) = V_0 \pm \frac{M^2}{2}\phi^2 \,. \tag{25}$$

With the positive sign the potential in Eq. (25) is an approximation for the simplest model of hybrid inflation well above the scale of the end of inflation; in this case ϕ decreases during the inflationary expansion. With the negative sign the potential in Eq. (25) is a simple small field inflation model, again far from the end of inflation; in this case ϕ increases during the inflationary expansion. In the following we use the approximate solution for the square of the inflaton as:

$$\phi^2(N) \simeq \phi_i^2 e^{\mp 2 \frac{M^2 M_{\rm pl}^2}{V_0}(N-N_i)} \,, \tag{26}$$

valid when $H \simeq \sqrt{V_0/(3M_{pl}^2)}$, i.e. $\frac{M^2}{V_0}|\phi^2 - \phi_i^2| \ll 1$.

Let us now compare the mean square of first order quantum fluctuations of the test fields with a small effective mass introduced above with that of the first order Mukhanov variable. For the inflationary zoo chosen the results are the following.

Chaotic quadratic inflation

The growth of a test field with constant mass m_χ is described by [5, 6]

$$\langle \chi^{(1)2} \rangle = \frac{3H^{2\frac{m_\chi^2}{m^2}}}{8\pi^2(2m^2 - m_\chi^2)} \left(H_i^{4-2\frac{m_\chi^2}{m^2}} - H^{4-2\frac{m_\chi^2}{m^2}}\right) . \tag{27}$$

For the case $m_\chi^2 = cH^2$, using Eq.(16), we obtain [6]

$$\langle \chi^{(1)2} \rangle = \frac{m^2}{6\pi^2}\left[\left(1 - e^{-\frac{2}{3}cN}\right)\left(\frac{9}{4c^2} + \frac{3}{2c}N_T\right) - \frac{3}{2c}N\right] , \tag{28}$$

where $N_T = \frac{3H_i^2}{2m^2}$ is equal to maximal number of possible e-folds in this chaotic model. In the limiting case $c \to 0$ and at the end of inflation ($N = N_T - 3/2$), we recover the result[1]:

$$\langle \chi^{(1)2} \rangle \simeq \frac{m^2}{12\pi^2} N_T^2 = \frac{3H_i^4}{16\pi^2 m^2} \,. \tag{29}$$

For a nonminimally coupled scalar field the integral in Eq.(18) can be easily computed in a closed form in terms of the exponential integral function $E_\nu(z)$ (see, for example,

---

[1] This corresponds to the massless limit of moduli production computed in Eq. (15) of [5] for $\alpha \to 0$.

[20]). One finds

$$\begin{aligned}\langle\chi^{(1)\,2}\rangle \;\simeq\; & \frac{m^2}{6\pi^2}\frac{e^{8\xi(N_T-N)}}{(N_T-N)^{2\xi}}\Big[(N_T-N)^{2+2\xi}E_{-1-2\xi}\big(8\xi(N_T-N)\big) \\ & -(N_T-N_i)^{2+2\xi}E_{-1-2\xi}\big(8\xi(N_T-N_i)\big)\Big]\,. \end{aligned} \tag{30}$$

One can verify that in the limit $\xi\to 0$ at the end of inflation and a fixed large value for N_T, the result of Eq.(29) for a massless modulus is again reobtained. To conclude, for the Mukhanov variable Eq.(21) gives [3, 5, 6]

$$\langle Q^{(1)\,2}\rangle = \frac{H_i^6 - H^6}{8\pi^2 m^2 H^2}\,. \tag{31}$$

The comparison between these results is showed in Fig.1.

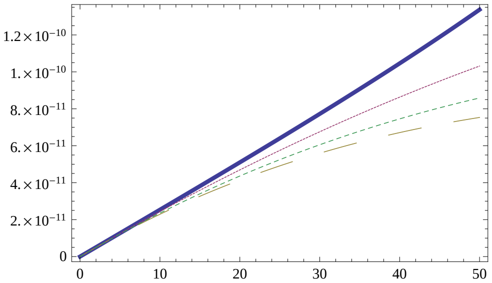

FIGURE 1. Evolution of the mean square quantum fluctuations (in units of $m_{\rm pl}^2$) versus the number of e-folds N for the quadratic chaotic model. We have chosen the inflationary trajectory with $m = 10^{-6}\,m_{\rm pl}$ and $H_i = 10\,m$. The mean square Mukhanov variable (thick line) dominates over those of test fields ($m_\chi \simeq 0.3m$ is the solid line, $c = 0.02$ is the dashed line, $\xi = 0.001$ is the dotted line).

Power-law inflation model

The growth of a test field with constant mass m_χ is described by [5, 6]

$$\begin{aligned}\langle\chi^{(1)\,2}\rangle \;=\; & \frac{p}{8\pi^2}H_i^2\exp\left(-\frac{p}{3}\frac{m_\chi^2}{H^2}\right)\left[-\exp\left(\frac{p}{3}\frac{m_\chi^2}{H^2}\right)\frac{H^2}{H_i^2}\right. \\ & \left.+\frac{p}{3}\frac{m_\chi^2}{H_i^2}Ei\left(\frac{p}{3}\frac{m_\chi^2}{H^2}\right)+\exp\left(\frac{p}{3}\frac{m_\chi^2}{H_i^2}\right)-\frac{p}{3}\frac{m_\chi^2}{H_i^2}Ei\left(\frac{p}{3}\frac{m_\chi^2}{H_i^2}\right)\right]\,, \end{aligned} \tag{32}$$

where E_i is the exponential integral function ([20]).

For the case $m_\chi^2 = cH^2$

$$\langle\chi^{(1)\,2}\rangle = \frac{p}{8\pi^2}H_i^2\left(c\frac{p}{3}-1\right)^{-1}\left(e^{-2\frac{N}{p}} - e^{-\frac{2}{3}cN}\right)\,. \tag{33}$$

For a nonminimally coupled scalar field

$$\langle\chi^{(1)2}\rangle = \frac{p}{8\pi^2}H_i^2\left(-2\xi-1+4p\xi\right)^{-1}\left(e^{-2\frac{N}{p}} - e^{\xi N\left(\frac{4}{p}-8\right)}\right), \tag{34}$$

and, to conclude, for the Mukhanov variable, one obtains

$$\langle Q^{(1)2}\rangle = \frac{p}{8\pi^2}\left(H_i^2 - H^2\right), \tag{35}$$

which at late times (see also [21]) becomes $\langle Q^{(1)2}\rangle = \frac{pH_i^2}{8\pi^2}$.

Fig. 2 presents comparison of results for the test fields and for the Mukhanov variable in the case of this second inflationary model.

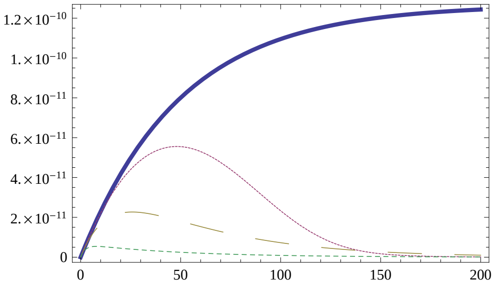

FIGURE 2. Evolution of the mean square quantum fluctuations (in units of $m_{\rm pl}^2$) versus the number of e-folds N for the exponential potential. We have chosen the inflationary trajectory with $p = 100$ and $t_i = 10^7\, m_{\rm pl}^{-1}$. The mean square Mukhanov variable (thick line) dominates over those of test fields ($m_\chi = 10^{-6}\, m_{\rm pl}$ is the solid line, $c = 0.1$ is the dashed line, $\xi = 0.05$ is the dotted line).

Small field inflation and Hybrid inflation models

Let us consider the potentials in Eq. (25), in the lowest order approximation; that is, for $V \simeq V_0 = 3H_0^2 M_{pl}^2$.

For the case of the growth of a test scalar field with constant mass we have

$$\langle\chi^{(1)2}\rangle \simeq \frac{3H_0^4}{8\pi^2 m_\chi^2}\left(1 - e^{-\frac{2m_\chi^2}{3H_0^2}N}\right). \tag{36}$$

Let us note that the corrections induced by a non-zero $M^2\phi^2/V_0$ term are typically small both for the case of hybrid inflation as well as for small field inflation (as long as the field does not grow too much due to instability).

For the case $m_\chi^2 = cH^2$ we have

$$\langle\chi^{(1)2}\rangle = \frac{3H_0^2}{8\pi^2 c}\left(1 - e^{-\frac{2}{3}cN}\right), \tag{37}$$

while, for a nonminimally coupled scalar field one obtains

$$\langle\chi^{(1)2}\rangle = \frac{H_0^2}{32\pi^2\xi}\left(1 - e^{-8\xi N}\right). \tag{38}$$

For the Mukhanov variable we obtain, by solving Eq. (19) using the expression in Eq.(26) with no further approximations, the following result

$$\langle Q^{(1)2}\rangle \simeq \pm \frac{4V_0^2(1-y)+3M^4\phi_i^2 y\left(4M_{pl}^2(N-N_i)+\phi_i^2(1-y)\right)\pm y(1-y^2)\frac{M^6}{4V_0}}{96\pi^2 M^2 M_{\rm pl}^4\left(1\pm y\frac{M^2\phi_i^2}{2V_0}\right)^2}, \quad (39)$$

where we have set $y=y(N)=e^{\mp\frac{2M^2M_{\rm pl}^2}{V_0}(N-N_i)}$. From this expression, when analyzing the hybrid inflation case, one can notice that the fluctuations have a maximum for a certain amount of e-folds N and then decay to the asymptotic value for a large N.

Comparison of mean squares of fluctuations for these last two models is presented in Figs. 3 and 4. For the hybrid model, quantum fluctuations of test fields with a small effective mass can dominate the Mukhanov variable, because of the presence of the leading constant term in the potential.

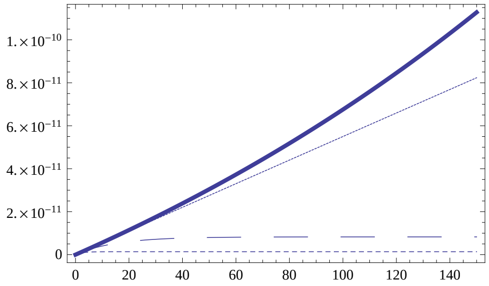

FIGURE 3. Evolution of the mean square quantum fluctuations (in units of $m_{\rm pl}^2$) versus the number of e-folds N for the small field inflationary model. For the inflationary background we have chosen $V_0 = 2.6\times10^{-12}m_{\rm pl}^4$, $M = 0.85\times10^{-6}m_{\rm pl}$ and $\phi_i = 0.3\,m_{\rm pl}$ as parameters. The mean square Mukhanov variable (thick line) dominates over those of test fields ($m_\chi = 10^{-2}H_0$ is the solid line, $c = 0.1$ is the dashed line, $\xi = 0.05$ is the dotted line).

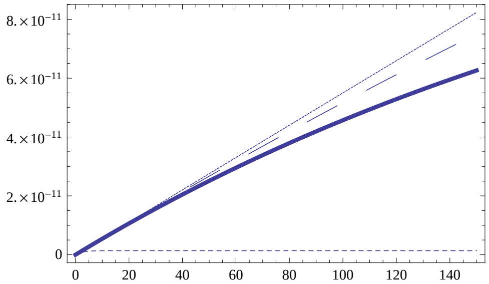

FIGURE 4. Evolution of the mean square quantum fluctuations (in units of $m_{\rm pl}^2$) versus the number of e-folds N for the hybrid model. For the inflationary background we have chosen $V_0 = 2.6\times10^{-12}m_{\rm pl}^4$, $M = 1.8\times10^{-6}m_{\rm pl}$ and $\phi_i = 0.3\,m_{\rm pl}$ as parameters. In this case the mean square of moduli can dominate over the mean square of Mukhanov variable (thick line): the parameters chosen are $m_\chi = 10^{-2}H_0$ (solid line), $c = 0.002$ (dashed line), $\xi = 0.05$ (dotted line).

VI. CONCLUSIONS

We have discussed the stochastic approach for general scalar fluctuations, which may have a nonzero homogeneous mode, in a generic model of inflation. We show, by using the field theory results as a guideline, that the stochastic equations for the canonical gauge invariant variable associated with such scalar fluctuations are naturally formulated as a flow in terms of the number of e-folds N.

We have then studied in detail the growth of quantum fluctuations in realistic inflationary models with $\dot{H} \neq 0$. We have selected four different potentials as representative examples of the *inflationary zoo* and different types of nearly massless fluctuations, including inflaton ones.

We have found that for most of the inflationary models, the mean square of the gauge invariant Mukhanov variable dominates over those of moduli with a non-negative effective mass. Hybrid inflationary models can be an exception: the mean square of a test field can dominate over that of the gauge invariant Mukhanov variable on choosing parameters appropriately. Our findings show that the understanding of inflaton dynamics including its quantum fluctuations is more important than the moduli problem in most of the inflationary models.
